

1. Computation Equation

Class-conditional:

$$P_{x|\mu, \Sigma} = G(x, \mu, \Sigma)$$

where

$$\Sigma = \frac{1}{N} \sum_{i=1}^N \left(x_i - \frac{1}{N} \sum_{i=1}^N x_i \right) \left(x_i - \frac{1}{N} \sum_{i=1}^N x_i \right)^T$$

Gaussian prior:

$$P_{\mu}(\mu) = G(\mu, \mu_0, \Sigma_0)$$

where μ_0 and Σ_0 is known. The following is the computation equations of different classification methods.

a) predictive distribution:

$$P_{x|T}(x|D) = G(x, \mu_n, \Sigma + \Sigma_n)$$

where

$$\begin{aligned} \mu_n &= \Sigma_0 \left(\Sigma_0 + \frac{1}{N} \Sigma \right)^{-1} \mu_{ML} + \frac{1}{N} \Sigma \left(\Sigma_0 + \frac{1}{N} \Sigma \right)^{-1} \mu_0 \\ \Sigma_n &= \Sigma_0 \left(\Sigma_0 + \frac{1}{N} \Sigma \right)^{-1} \frac{1}{N} \Sigma \end{aligned}$$

b) MAP:

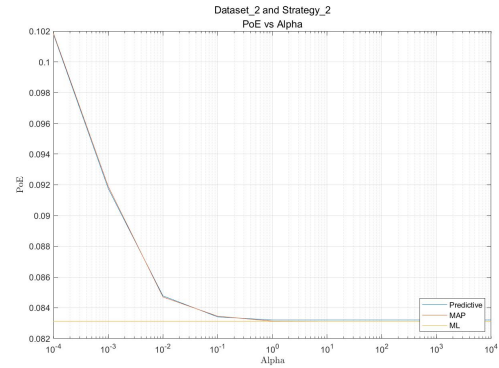

$$P_{x|T}(x|D) = G(x, \mu_n, \Sigma)$$

c) ML:

$$P_{x|T}(x|D) = G(x, \mu_{ML}, \Sigma)$$

2. Curves of Classification Error vs α

3. Observation and Explanation

a) The relative behavior of these three curves.

Observation: in strategy 1, the ML line is a constant (horizontal) line. The PoE corresponding to MAP solution increases as alpha increases, and finally converges to ML line.

The PoE corresponding to predictive solution increases as alpha increases, and finally goes to a constant value. This constant value is obviously smaller than ML in dataset1, a little bit bigger than ML in dataset2 and a little bit smaller than ML in dataset3&4. In strategy 2, things would be different, but we will discuss in section (c).

Explanation: ML line is a constant (horizontal) line because ML method has nothing to do with alpha. As alpha increases, the prior information becomes more uncertain, making the PoE of MAP and predictive solution increases. For the MAP solution, increase of alpha would push μ_n more and more closet to μ_{ML} , and finally let the MAP solution and ML solution nearly the same when alpha is large enough. For the predictive solution, increase of alpha would also push μ_n more and more closet to μ_{ML} . Meanwhile, Σ_n would approximate to $\frac{1}{N}\Sigma$, leading $\Sigma + \Sigma_n$ approximate to $\Sigma + \frac{1}{N}\Sigma$. Hence predictive solution would go to a constant value when alpha is large enough. This constant value varies depending on sample number in different dataset. That is why we can see the constant values in dataset1,2,3&4 are different.

b) How that behavior changes from dataset to dataset.

Observation: the PoE corresponding to predictive solution is obviously smaller than MAP solution in dataset1. However, in dataset2,3&4, PoE of predictive solution and MAP solution are nearly the same. In dataset2, predictive solution performs a little worse than MAP solution. But in dataset3&4, predictive solution performs a little better than MAP solution.

Explanation: when sample number of dataset (for example, dataset1) is relatively small, then predictive solution use more information of prior, leading predictive solution performs better than MAP solution and ML solution. However, when sample number is relatively large (for example, dataset2,3&4), $\Sigma + \Sigma_n$ would approximate to Σ , making predictive solution performs nearly similiar with MAP solution. However, when the alpha is large enough, they will converge to constant value, as discuss in section (a). The final PoE differ depending on sample number but the difference is small because at this time, the impact of alpha is predominant.

c) How all of the above change when strategy 1 is replaced by strategy 2?

Observation: In strategy 2, at a small alpha, PoE of predictive solution and MAP solution are obviously worse than ML solution. As alpha increases, PoE of predictive solution and MAP solution would decrease. As for MAP solution, it would again converges to ML line when alpha is large enough. The reason is the same as we discuss in section(a). As for predictive solution, in dataset1, predictive solution performs obviously better than MAP solution. The final constant PoE is also obviously better than MAP and ML solution. But in dataset2,3&4, performance of predictive solution is nealy similiar with MAP solution. The reason is the same as we discuss in section (b).

Explanation: The difference between strategy 1 and strategy 2 is the mean of first DCT coefficients. We plot the marginal distribution of first DCT coeffiience in Homework2 and

already find the obvious difference of mean between background and foreground. Hence strategy 2 actually provides a bad prior information and play a bad guide. Predictive solution and MAP solution use information from prior, so in strategy 2, when alpha is relatively small, PoE of predictive solution and MAP solution is obvious large than ML solution. But when alpha increases, the prior becomes less important and ML estimation becomes predominant. Hence MAP solution would converges to ML line, and predictive solution would go to constant value.

Appendix

The following is the Matlab code.
